

TIME STRETCHING OF THE GEV EMISSION OF GRBS: FERMI-LAT DATA VS GEOMETRICAL MODEL

M. S. Piskunov^{1,*}

¹Institute for Nuclear Research, Moscow, Russia

Numerous observations confirm that the high energy (> 100 MeV) emission of gamma ray bursts is delayed with respect to the low energy emission. However, the difference of light curves in various high energy bands has not been studied properly.

In this paper we consider all the bursts observed by Fermi Large Area Telescope (LAT) since 2008 August 4 to 2011 August 1, for which at least 10 events with energies 1 GeV or higher were observed. There are 4 of them: 080916C, 090510, 090902B, and 090926A. We study their light curves in two bands, (100 MeV, 1 GeV) and (1 GeV, 300 GeV). The Kolmogorov-Smirnov test is used to check whether the light curves for these two bands are the same. No significant difference was found for 080916C and 090510. However, we observed with statistical significance of 3.3σ , that the higher energy light curve of 090926A is stretched with respect to the lower-energy one, and with statistical significance of 2.2σ , that the lower energy light curve of 090902B is stretched with respect to the higher-energy one.

We suggest a simple geometrical model to explain this result. The main assumption is the jet opening angle dependence on radiation energy – the most energetic photons are emitted near the axis of the jet. We also assume that all bursts are the same in their rest frames (that is their light curves differ because of different redshifts and observer's off-axis angles). To test this model, we compute the total energy of the burst, and confirm that it is below the constraint. We also compute the fraction of observable bursts in (100 MeV, 1 GeV) band, which can also be observed in higher energies. This fraction matches the observations. Finally, we predict the distribution of observable stretching factors, which may be tested in the future when more observational data will be available.

1. INTRODUCTION

Gamma Ray Bursts (GRBs) are among the most energetic events in the Universe, therefore they might provide new knowledge for particle physics. Modern observatories, specifically Fermi [5] and Swift [8] made possible to study these explosions extensively [9, 16]. These and previous studies led to several interesting results. For example, the total energy emitted in gamma-rays during a burst was found to be similar among different bursts within an order of magnitude [6]. This suggests that most of the bursts must have similar energetics in their rest frame. Temporal variations of spectra were also studied. The spectral lags were found between different low energy bands [17]. The very high energy radiation was discovered to be extended relative to x-ray emission [7, 10, 16]. In this study we continue this research and explore the spectral variations between energy bands (100 MeV, 1 GeV) and (1 GeV, 300 GeV) (we call them low and high energy bands throughout the paper). We use the Kolmogorov-Smirnov (KS) test to compute the time stretching of radiation in one of these bands compared to the other. Results obtained with this approach are discussed in section 2. Then we propose a simple geometrical model to explain these results in section 3. Finally, our study is summarized in section 4.

2. FERMI LAT DATA

We take the GRB list from the Fermi-LAT catalog [2], and use the technique introduced in [12] to estimate background radiation in both energy bands.¹ Most of the bursts in the catalog, however, do not have enough events with over 1 GeV energies to do desired computations, so we choose only those bursts, from which at least 10 photons were detected in the high energy band. This leaves 4 of them: 080916C [15], 090510 [3], 090902B [1] and 090926A [4].

For these 4 bursts we compute both high and low energy distributions of photon observation times, that is the distributions of time intervals from the burst start to the photon detection in observer's reference frame, in which burst starts are taken to be the beginning

* Electronic address: maxitg@icloud.com

¹ Detailed description of computations in this and the next section (including the source code) can be found on GitHub: <https://github.com/maxitg/GammaRays>

of the LAT interval from the Table 4 of [2].

Then we subtract the background, which is considered linear for the duration of the burst (light curves on figures 1 and 2 are presented with background subtracted):

$$\Phi_i(t) = \frac{p_i(T_1, t) - b_i \frac{t-T_1}{T_2-T_1}}{p_i(T_1, T_2) - b_i} \quad (1)$$

Here (T_1, T_2) is the time range of observations, $p_i(t_1, t_2)$ is the number of photons observed in the time range t_1 to t_2 in the i 's energy band (i is either low or high for the low and high-energy bands respectively), and b_i is the estimated number of background photons for the time range T_1 to T_2 in the i 's energy band. The background to signal ratio $\frac{b_i}{p_i(T_1, T_2)}$ is the largest for GRB 090902B and equals 6.5%.

The number of degrees of freedom used as an input for the KS-test is $p_i(T_1, T_2) - b_i$. This is lower than the number of independent photons and therefore we are conservative when estimating the probability and significance of the effect. The KS-probabilities are computed for pairs $\Phi_{\text{low}}(t), \Phi_{\text{high}}(\kappa t)$ to obtain the allowed ranges for stretching factors κ for a given confidence level.

Finally, we stretch the high energy cumulative distribution function (CDF) by different factors, and compare it to the low energy CDF using the KS-test. If we require 2σ -significant probability to exclude a particular stretching factor, then the stretching factor of 1 (which means no stretching) is allowed for GRBs 080916C and 090510. For the other two bursts the stretching factor of 1 is, however, prohibited. For GRB 090902B, it is smaller than 1, so the low energy light curve is stretched with respect to high energy one (see fig. 1). And for GRB 090926A, even more dramatic deviation for the stretching factor of 1 is observed in the opposite direction. The high energy light curve of GRB 090926A is stretched with respect to low energy one with a factor of at least 1.99 (see fig. 2). You can see allowed ranges for stretching factors for all the bursts studied in table 1.

So we obtained a preliminary (for significance is less than 5σ) result that the stretching factors for observable bursts might be both larger and smaller than 1.

3. MODEL

We propose that time stretching of GRB light curves can be explained by the curvature effects (that is the effects of jet geometry) even if all the bursts are the same in their rest

frames. These effects were explored by multiple authors [11, 13, 14]. However, these studies were only concerned with x-ray radiation, and, even more importantly, they assumed that the distribution of radiation sources is homogeneous throughout the jet. We propose a contrary idea: that the highest energy radiators are concentrated near the axis of the burst, meaning that the burst opening angle depends on energy. We cannot prove this assumption rigorously, but have arguments supporting it.

First of all, there are around 750 GRBs detected by Gamma-ray Burst Monitor (GBM), half of which were in the LAT field of view at the moment of observation [16]. However, only about 30 of them were detected by the LAT, and only 4 of them were bright in the high energy band. If we extrapolate the uniform jet model to very high energies, this observation would mean that these groups of bursts are internally different: some of them produce very high energy (VHE) radiation, and other do not. These differences are hard to explain given that burst energetics are similar [6]. Nevertheless, these differences in burst counts can easily be explained by our model. In our model, the opening angle of a jet is inversely proportional to the energy of photons it radiates. Therefore the most common scenario is that the off-axis angle of the observer is smaller than the low energy jet opening angle, but larger than the opening angle of a high energy jet. Because of that, most of the bursts can only be seen at low energies. The 4 bursts we study in this paper were seen, according to our model, from the lowest off-axis angles.

Second, consider the plasma right after its ejection from the central engine. Two processes happen here simultaneously:

1. Particles near the jet boundary change their movement directions, therefore increasing the opening angle of the jet.
2. Particles lose energy, therefore decreasing radiation frequency emitted by the jet.

We argue that these two processes are correlated, for they happen due to the same particle interaction processes. And since they are correlated, jets with larger opening angles should have lower energies, which is the assumption we are trying to justify.

You can see why this assumption allows for non-trivial stretching factors in the figure 3. More rigorously, the model is defined by the following assumptions:

1. Time $t = 0$, a spherical (yet anisotropic) shell of plasma is emitted. The center is called the central engine.

2. The shell points propagate with a constant velocity $v = \frac{\sqrt{\gamma^2-1}}{\gamma} \sim 1$, so at the time t the radius of the shell is vt .
3. Each point of the shell is an isotropic radiator in its rest frame.
4. The radiation intensity is a function of the radiator position and the radiation frequency:

$$\eta(r, \theta, \omega) = \frac{\eta_0}{1 + \left(\frac{r}{r_0}\right)^n} \exp\left(-\left(\frac{\theta}{\theta_0}\right)^2 \left(\frac{\omega}{\omega_0}\right)^{-2k}\right) \left(\frac{\omega}{\omega_0}\right)^\alpha \quad (2)$$

η is the number of particles emitted per volume per solid angle per frequency. It is a function of the distance r from the central engine, the off-axis angle θ , and the radiation frequency ω .

In order to compute parameters of the radiation intensity function (which are assumed to be the same for all bursts), we fit them to minimize the cost function designed to satisfy the following objectives:

- Total energy of the burst is finite (that is $k + \frac{\alpha}{2} + 1 < 0$) and smaller than $6 \times 10^{53} \text{ GeV} \approx 10^{51} \text{ erg}$ [9]. Note that this energy is the same for all bursts because they are assumed to be the same in their reference frames.
- The stretching factor of the burst should be compatible with the value for the GRB 090926A.
- The ratio of photons with high energies and low energies should be compatible with the value 0.057 for GRB 090926A.
- The burst should not be too faint compared to other bursts from the sample. In other words, the total number of observed photons should approximately equal to the median among the sample.
- We assume that all bursts have the same burst parameters $(\gamma, \eta_0, r_0, n, \omega_0, \theta_0, k, \alpha)$ and require that bursts with small stretching factors like GRB 090902B should be possible to observe. So we require that bursts with the stretching factor of GRB 090902B or lower appear in random samples by varying z and χ . Note that this requirement unlike others applies to an ensemble of simulated bursts.

The minimization converged to the following parameter values:

- $\gamma = 300$, the relativistic factor of the shell, $\gamma \gg 1$.
- $\eta_0 = 8.15 \times 10^{34} \text{ sec}^{-3} \text{ GeV}^{-1}$, which defines the luminosity scale.
- $r_0 = 3.36 \times 10^6 \text{ sec}$, the characteristic jet length; $r_0 \ll \frac{1}{H(0)}$, $H(t)$ is the Hubble parameter;
- $n = 22.5$, which determines the sharpness of the jet end, $n > 3$;
- $\omega_0 = 1 \text{ GeV}$, a characteristic radiation frequency;
- $\theta_0 = 5.02 \times 10^{-5}$, the opening angle of the jet for radiation with frequency ω_0 , $\theta_0 \ll 1$;
- $k = -0.700$, which determines how much the opening angle changes with frequency, $k < 0$;
- $\alpha = -0.627$, the bare spectral index, $\alpha < -2k - 1$

Numerical simulations based on these assumptions are able to reproduce both stretching factors smaller than 1 (like of GRB 090902B) and larger than 1 (like of GRB 090926A) depending on redshift and observer's off-axis angle (see fig. 4).

To test the model against observations, we computed a few properties of the burst sample obtained by selecting redshifts and off-axis angles randomly (respecting the actual spacial distribution of GRBs):

- Distribution of stretching factors of observable bursts. Only those bursts are included in this distribution, for which at least 10 photons with energies 1 GeV or higher are observed. You can see the PDF and the CDF on fig. 5. This distribution doesn't contradict with the values of stretching factors obtained in section 2.
- The fraction of bursts observable (that is, at least 10 particles are observed in a given energy range) in low energy band, which are also observed in high energy band $f_m = 0.116$. The Fermi LAT catalog [2] contains 35 bursts out of which 4 can be observed in high energy band. Therefore the observed value $f_o = 0.11 \pm 0.05$ (error obtained from binomial distribution) agrees with the model.

- There is a correlation between the fraction of high energy photons (that is high energy photon count divided by the total photon count), the stretching factor and the observer's off-axis angle (see fig. 6). It allows one to predict observer's off-axis angles.

So our model, though with some discrepancies (listed in the next section), is able to explain the time stretching result from section 2.

4. DISCUSSION

The main results of our study may be summarized as following:

1. The time stretching of GRB light curves between different VHE bands is confirmed with statistical significance of 3.3σ (that is the probability of no stretching is 9.7×10^{-4}).
2. This time stretching can be explained by geometry of the jet, without introducing any new spectral components.
3. Stretching factors both larger and smaller than one can be reproduced without varying internal burst parameters (that is assuming all bursts to be the same in their reference frames).

There are, however, directions for improvement:

- The model prediction and observations on fig. 6 are, though close, not exactly agree.
- Shapes of light curves produced by the model differ considerably from observed ones.
- Assumption of energy dependence on off-axis angle should be better justified (with a thermodynamic simulation of jet plasma, for example).
- While we believe that all bursts are almost the same in their rest frames, they are certainly not exactly the same. The minor differences between GRBs might be responsible for observable deviations from the model predictions.

We think, however, that these problems are not unresolvable, and may be addressed by refining the model without changing its main assumptions.

ВРЕМЕННОЕ РАСТЯЖЕНИЕ ГЭВ ИЗЛУЧЕНИЯ ГАММА-ВСПЛЕСКОВ: FERMI LAT И ГЕОМЕТРИЧЕСКАЯ МОДЕЛЬ

М. С. Пискунов

Наблюдения показывают, что излучение гамма-всплесков с энергией выше 100 МэВ систематически наблюдается позже, чем низкоэнергичное излучение. Различия же кривых блеска в различных диапазонах высокоэнергичного излучения (> 100 МэВ) изучены хуже.

В данной работе мы изучаем различия кривых блеска в диапазонах (100 МэВ, 1 ГэВ) и (1 ГэВ, 300 ГэВ). Для исследования выбраны все 4 гамма-всплеска из каталога Fermi, наблюдения которых содержат не менее 10 фотонов с энергией > 1 ГэВ: 080916C, 090510, 090902B, 090926A. Кривые блеска 080916C и 090510 в двух рассматриваемых диапазонах не различаются статистически значимо, однако для 090926A установлено со статистической значимостью 3.3σ , что излучение в диапазоне (1 ГэВ, 300 ГэВ) растянуто относительно менее энергичного, также для 090902B установлено со статистической значимостью 2.2σ , что излучение в диапазоне (100 МэВ, 1 ГэВ) растянуто относительно более энергичного.

Мы предлагаем простую геометрическую модель, объясняющую этот результат. Основное предположение – чем выше энергия излучения, тем ближе к оси джета оно излучается. Мы также предполагаем, что все всплески одинаковы в собственной системе отсчета (то есть, различия кривых блеска объясняются исключительно разницей в красном смещении и углом наблюдения). В рамках модели соблюдается ограничение на максимально допустимую энергию всплеска. Также получена доля всплесков среди наблюдаемых в диапазоне (100 МэВ, 1 ГэВ), которые также можно увидеть в диапазоне (1 ГэВ, 300 ГэВ). Полученная доля согласуется с наблюдениями. Наконец, предсказано распределение коэффициентов растяжения, которое может быть проверено по мере накопления наблюдений.

Tab. 1. Stretching factor computation results for the bursts studied. Ranges of allowed stretching factors are shown for studied bursts for multiple levels of significance. The values for trigger time and location are taken from the tables 2 and 4 of [2].

Fig. 3. Model Overview. Here lighter and darker cones represent the regions through which low and high energy plasma propagates. In case depicted the observer's off-axis angle is smaller than the opening angle of the low energy jet, so, due to the relativistic beaming effect, the most of the observable low energy photons will travel along the straight line from the central engine. Also, the observer's off-axis angle is larger than the opening angle of the high energy jet, so the high energy radiation will still originate near the center of the jet (because it is the only place where there are high energy radiators). The observation time of a photon is a sum of two things: the time interval spent in plasma as a radiator (which approximately equals to the distance from the central engine to the point of emission); and the time interval from emission to detection (which is the distance from the point of emission to the observer's location). Given a position of the shock front, this sum is larger for high energy photons. Because of that, high energy emission will be observed later throughout the burst duration, therefore the high energy light curve will be stretched.

Fig. 4. High and low energy light curves produced by the geometrical model. Burst parameter values are the same as discussed in section 3. On the left panel: the stretching factor $\kappa = 0.821$, redshift $z = 1.82$, off-axis angle $\chi = 0$. On the right: stretching factor $\kappa = 2.26$, redshift $z = 2.106$, off-axis angle $\chi = 5.41 \times 10^{-3}$.

Fig. 5. Stretching factors histogram and CDF produced by our model. The sample contains 4096 bursts. Numbered error bars correspond respectively to GRB 080916C, GRB 090510, GRB 090902B and GRB 090926A.

Fig. 6. Correlations between off-axis angles, stretching factors and high to low energy photon count ratios found in the sample produced by our model. The sample contains 4096 bursts. Numbered black crosses show data respectively for GRB 080916C, GRB 090510,

GRB 090902B and GRB 090926A with 2σ error bars. This correlation allows one to estimate off-axis angles of observed bursts.
